JULY 2025

THE REPUBLIC OF UGANDA

POPULATION PROJECTIONS 2025-2050

National and District

VOLUME I

JULY 2025

This report presents mid-year population projections for 2025-2050 following release of the National Population and Housing Census (NPHC) 2024 final results. The Census was undertaken by the Uganda Bureau of Statistics (UBOS).

Additional information about the Census may be obtained from the UBOS Head Office, Statistics House. Plot 9 Colville Street, P. O. Box 7186, Kampala, Uganda; Telephone: +256-414 706000; E-mail: ubos@ubos.org; Website: www.ubos.org

RECOMMENDED CITATION: Uganda Bureau of Statistics 2025, Population Projections 2025-2050 – National and District (Volume I), Kampala, Uganda.

PREFACE

I am pleased to present to you the Population Projections 2025 – 2050 Report which has been developed by the Uganda Bureau of Statistics (UBOS) to offer insights into Uganda’s future demographic landscape post the National Population and Housing Census (NPHC) 2024. The NPHC 2024 was a decennial exercise undertaken to provide up-to-date demographic, socioeconomic, and housing data to support research, policy formulation, and planning for national development.

In the period between the NPHC 2024 and the next census, however, there will still be need for current population statistics to effectively continue tracking progress of the national development targets. To address this, UBOS has developed Population Projections 2025–2050 with estimates on Uganda’s future population trends and highlights key demographic changes that may impact the country's development trajectory. The projections are presented by single years of age and sex at the national level, and by sex at the district level.

UBOS appreciates the partnership with development partners, notably the United Nations Population Fund (UNFPA) and the United Nations Department of Economic and Social Affairs (UNDESA), for their financial and technical support during the process of generating this Population Projections 2025 – 2050 Report. We would like to extend our gratitude to all the staff involved in analysis and report writing for the Population Projections 2025–2050 Report with commitment, dedication, and hard work.

The Bureau appeals to decision makers, researchers and academicians to make extensive use of this statistical information for planning, policy analysis, evidence-based decision-making and public debates.

INTRODUCTION

1.1 Background

The 2024 National Population and Housing Census (NPHC) was a comprehensive enumeration of all persons and households in Uganda as of census night, 9th May 2024. The census was conducted to generate reliable and accurate data to inform evidence-based decision-making, and to support the implementation and monitoring of progress on national, continental, and global development agendas. It provides detailed information on population size, composition, and structure, as well as housing conditions and household characteristics. This data is essential for effective planning and policy formulation by Ministries, Departments, and Agencies (MDAs), and also serves as a valuable resource for researchers, academic institutions, and the private sector.

Uganda has been conducting censuses at decennial intervals. While these censuses provide valuable data at specific points in time, the population continues to change substantially between them. As such, there is a need to generate updated information on population changes in the post-census period to support effective planning and development initiatives. Population projections are therefore essential to bridge data gaps between censuses and provide a basis for informed decision-making. More importantly, these projections play a critical role in monitoring and evaluating progress toward achieving national development goals, the African Union Agenda 2063, and the Global Agenda 2030 or Sustainable Development Goals (SDGs).

Population projections are carefully constructed approximations of future population size and characteristics based on assumptions about fertility, mortality, and migration trends. They are crucial for governments, researchers, and the private sector to plan for economic, educational, and health needs across different time frames. Reliable projections depend on high-quality base data and well-founded assumptions. Generally, projections are more accurate for shorter time spans and larger geographical areas.

This report presents the data sources, data evaluation, projection assumptions, projection methods, justification for population projections and projected figures at the disaggregated by sex and age from 2025 to 2050. A link to the detailed projected figures at national and subnational levels from 2025-2063 have been provided on the Bureau website (www.ubos.org).

1.2 Justification of Population Projections

Population projections are vital tools for guiding development planning and policy decisions at both the national and sub-national levels. They help shape strategies aimed at improving the quality of life for current and future populations. By providing insights into future population dynamics such as growth rates, age and sex composition, and spatial distribution these projections inform critical development choices. Consequently, population projections are essential components of a nation's development agenda, supporting sustainable and informed decision-making. Projections have remained the main source of data for indicative planning figures for both national and sub national planning and budgeting in the country.

METHODOLOGY

This report details the methodology, data sources, evaluation, modelling choices and assumptions, and analytical workflow for generating population projections for Uganda at the national and subnational (district) levels for the period 2025-2050. These projections are based on the results of the 2024 Population Census of Uganda, previous censuses, and demographic and health surveys, utilizing advanced analytical and statistical methods developed by the Population Division of the United Nations (United Nations, 2024) and new extensions for application at the subnational level.

2.1 Sources of Data

The baseline population and components of population change, such as fertility, mortality, and migration levels and trends, are essential for projecting future population size and structure. The figures presented in this report are based on data from the 2024 NPHC, complemented by information from previous population censuses conducted in 1991, 2002, and 2014 as well as seven rounds of the Demographic and Health Surveys conducted between 1988 and 2022.

2.2 Baseline Population and Census Data Evaluation

Population data, just like all demographic statistics derived from census, surveys, or administrative records, are subject to error. The extent of these errors depends on the accuracy of the data recording and completeness of coverage within the study area. Errors related to age and sex are among the most common. To produce accurate and reliable population projections for the period 2025–2050, it is crucial to evaluate the base data from the 2024 National Population and Housing Census (NPHC) to assess its accuracy for age misreporting and under enumeration. This section outlines the steps taken to appraise the quality of the 2024 NPHC data and follows the new UN protocol for evaluating and adjusting census population counts (Johnson et al., 2022).

2.2.1 Coverage errors

Coverage errors in population data can occur in several ways: by omitting individuals who should have been counted, duplicating entries, or including those who should not have been included. Despite extensive efforts to minimize these errors, such as providing comprehensive training to field staff, using updated cartographic maps, and applying rigorous checks and controls during fieldwork, some errors are still inevitable.

To evaluate the quality of the 2024 National Population and Housing Census, a Post Enumeration Survey (PES) was conducted in the month of June and July 2024. Population counts from the 2024 NPHC were assessed for geographical coverage, completeness, and other common data quality issues. The PES revealed an undercount of 4.3%, which was factored into the adjustment of the base population. The PES was instrumental in identifying the extent and distribution of under-enumeration, enabling adjustments at both national and sub-national levels overall and by age and sex, following an approach similar to that implemented by the United Nations (Johnson et al., 2022). Unlike the previous population projections, this is the first time the country has adjusted for undercount based on PES results.

2.2.2 Analysis of age distribution for digit preference and age heaping

Census data often show inconsistencies because people sometimes misreport their age, commonly by rounding to numbers ending at 0 or 5, a phenomenon known as age heaping or age misreporting. This makes the population's age distribution appear "spiky" instead of smooth. The method protocol developed by the United Nations to evaluate census population data by age and sex (Johnson et al., 2022) was applied to both the national and subnational levels for the 2024 census results.

This involved computing the Bachi index to measure the extent of this problem on the distribution of the population by a single year of age. This index compares the number of people reported at ages ending in specific digits to what would be expected if age were reported accurately.

For adults, the Bachi index is typically calculated for ages 23 to 77 and helps categorize the data quality. For instance, an index between 2 and 5 indicates "Approximate" data quality, between 5 and 15 means "Rough" data, and values up to 20 fall into the "Very Rough" category, signifying increasingly severe misreporting. These index values guide the selection of appropriate "smoothing" methods to correct age distribution, with higher index values requiring more intensive smoothing (Johnson et al., 2022).

At the national level in Uganda, the Bachi index for adults was 20.4 for the 1991 census, 10.8 for the 2002 census, 9.4 for the 2014 census, and 4.1 for the 2024 census indicating an overall improvement in data quality and age reporting over time. However, when the index was computed at the district level, the values ranged between 2.1 and 14.6 with a median of 4.3.

For children, a separate Bachi index was calculated for ages 3 to 17, recognizing different reporting

patterns in this age group. Although specific descriptive categories, such as those for adults, are not provided, an index between 1 and 8 still indicates varying degrees of age misreporting for children, requiring tailored smoothing procedures. Generally, lower Bachi values suggest better data quality and less need for adjustment, whereas higher values indicate worse quality and more significant smoothing is required.

At the national level in Uganda, the Bachi index for children was 4.9 for the 1991 census, 3.0 for the 2002 census, 2.8 for the 2014 census, and 1.8 for the 2024 census also indicating an overall improvement in data quality over time. However, when the index was computed at the district level, the values ranged between 1.0 and 8.7 with a median of 2.2.

On this basis, and to ensure consistency between district- and national-level age distributions, it was decided that it was best to use 5-year age group data instead of single-year data because the quality of the single-year age distribution is still deemed too deficient across all districts. In such cases, the population is analyzed, smoothed, and then "graduated" (converted) from 5-year age groups back into single-year age groups using different methods, as explained in the next section.

2.2.3 Analysis of 5-year age groups and graduation into single years

To assess the quality of 5-year age distributions, the age ratio score, which is a key component of the broader UN age-sex accuracy index, was used. This score quantifies the extent of age misreporting by summing the absolute differences between reported age ratios and expected smooth distribution (Johnson et al., 2022). For adults, this score is typically computed for ages 15-19 up to 70-74, while for children, it focuses on ages 0-4 to 10-14. For the 2024 census in Uganda, the age ratio for adults was 9.1 at the national level, and varied between 3.7 and 33.3 with a median of 11.0 at the district level. The age ratio for children was 1.3 at the national level, and varied between 0.3 and 19.4 with a median of 3.2 at the district level.

Once the data quality is assessed, a Moving Average (MAV) smoothing method is chosen to correct the age distribution, with the specific MAV level (e.g., MAV with N=1, 2, or 4) determined by the magnitude of the age ratio score and average years of education in the population. For example, lower age ratio scores and higher education levels might lead to minimal smoothing (MAV, N=1), while higher scores might require more aggressive smoothing (MAV, N=2 or N=4). Similarly, for children, smoothing was based on their age ratio score, with a maximum MAV of N=2. For the Uganda 2024 census, an MAV N=2 was used to smooth the empirical 5-year age group distributions, which led to an adjusted age ratio for adults of 2.5 at the national level, and between 2.1 and 9.5 with a

median of 3.3 at the district level. The adjusted age ratio for children was 1.3 at the national level and varied between 0.1 and 10.1 with a median of 2.0.

After smoothing the 5-year age groups, the data were graduated (i.e., redistributed) back into single-year ages using the modified Beers osculatory method implemented in the Demo Tools R package (Riffe et al., 2022), which provides smoother interpolated results than the default monotonic spline or the Sprague (Swanson & Siegel, 2004).

2.2.4 Extension of the open age group up to age 100+

For long-term population projections, it is crucial to have population data extending to very old ages, such as 100 years and over, even if a census only provides data up to age 95 or a similar open-ended age group as in the 2024 census in Uganda. To achieve this, the United Nations uses a generalized version of the OPAG approach (Arriaga et al., 1994) implemented within the Demo Tools R package (Riffe et al., 2022). This method works by assuming that the older population (beyond where census data are reliable) behaves like a "stable population." It uses a country's specific life table to guide this extension. The process involves two key steps: first, it identifies a growth rate that best matches the observed population in the last few age groups before the open-ended age group to this "stable population" concept; second, it redistributes the population from a selected starting age (to minimize any abrupt changes or "discontinuity") upwards, typically to age 105+, ensuring a smooth and consistent population distribution for these advanced ages. The national and district-level population based on the adjusted population census results obtained from the previous steps was further adjusted from age 85 onward up to age 100+ based on this method to obtain more coherent demographic age structures at older ages, consistent with the underlying recent life tables available at the national and subnational levels for Uganda.

2.2.5 Shift of the population from the census date to end-year

To prepare for annual population projections during civil calendar year, when a census is conducted on a specific date (e.g., May 9, 2024) and population figures are needed for the end of the year (or any other desired date), the initial census population needs to be "shifted" to the new target date. The MOVEPOP method developed by the US Census Bureau (Arriaga et al., 1994) was used and implemented in the R language to apply it at the national and district levels for the adjusted census population obtained from the previous steps. The process works by first calculating the population growth rate for the census date, considering vital demographic events such as births (from age-specific fertility rates), deaths (from age-specific death rates), and the net number of migrants for that year. This newly estimated growth rate was then applied to the census total to project the overall

population size to the desired end-of-year date. Finally, this new total population was distributed proportionally across all age and sex groups based on the original age and sex composition recorded in the census. This ensures that the baseline population for the start of the projections is coherently adjusted to the precise reference date, the population was projected from 9th May, 2024 (The census reference night) to 30th June, 2024 (for mid-year population projections) and to 31st December, 2024 for end of Year projections.

2.3 Projection methodology

The Cohort Component Method of Population Projection (CCMPP) was used for this analysis (United Nations, 1956, 2024). This is the most widely accepted and recommended method for projecting a population. CCMPP provides a structured framework for accounting for the three key demographic components of population change: fertility, mortality, and net migration.

Technically, CCMPP is not a standalone projection method because it relies on prior assumptions or projections of these components. Rather, it is a mathematical application specifically of matrix algebra that allows for the calculation of future populations by applying assumed trends in fertility, mortality, and migration to a base population, distributed by age and sex, through successive single-year intervals of time.

The method operates using the following fundamental demographic balancing equation:

$$P(t+1) = P(t) + B(t,t+1) - D(t,t+1) + NM(t,t+1)$$

where the population at the end of a year, $P(t+1)$, is equal to the population at the start of the year ($P(t)$) plus the number of births (B) minus the number of deaths (D) plus the net number of international migrants (NM) during that year. For each age cohort, the population is surviving forward to the next year and next age using age-specific survival ratios, with new births added to the 0-year-old age group.

Fertility, mortality, and migration paths for Uganda are built on the Bayesian probabilistic projection methods used by the United Nations for the World Population Prospects 2024 (United Nations, 2024) at the national level, with new extensions for sub-national projections at the district level based on the statistical relationships between each district and the national average over time.

The UN framework treats three demographic drivers — fertility, mortality, and migration — as stochastic processes. Every driver is modelled at the national level using Bayesian hierarchical techniques that borrow strength from both a country's history on the demographic drivers and the

global record. One thousand Monte Carlo trajectories were generated for each component; combining them with the cohort-component accounting engine produced an ensemble of equally plausible future populations. The median of the ensemble is the most likely path, whereas the surrounding distribution yields prediction intervals that quantify uncertainty.

A single run of the cohort-component model applies each triplet of fertility, mortality, and migration draws to the 2024 census baseline, producing one complete future population. Repeating these two thousand times yields the national bundle used throughout the report.

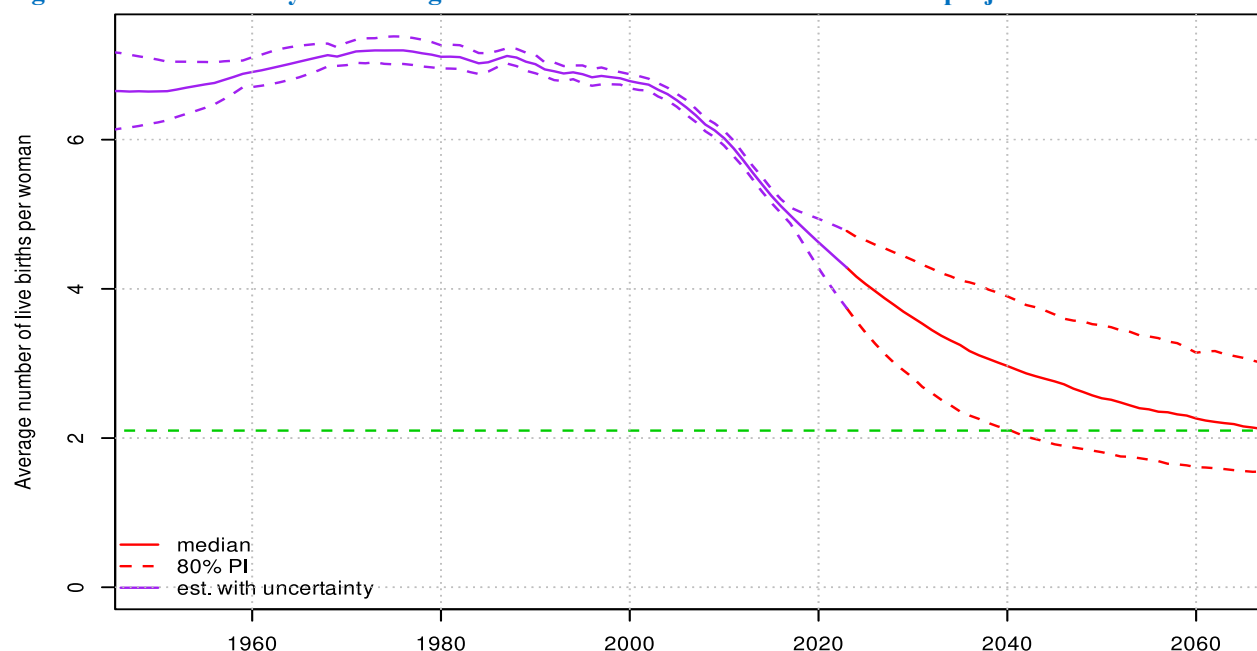

Recent methodological research demonstrates that subnational demography can also be handled probabilistically without estimating entirely new data-hungry models for each district. The approach plugs local information into transformations of the national trajectories, building on the respective differentials between each district and national average over time.

2.3.1 Estimating total fertility, age-specific fertility and the sex ratio at birth

Bayesian hierarchical models were used to estimate the annual time series of total fertility, age-specific fertility, and sex ratio at birth from 2025 to 2050 at the national level and for all districts. These models incorporated available empirical evidence from the 1991, 2002, 2014, and 2024 National Population and Housing Censuses and Uganda Demographic and Health Surveys (UDHS).

The total fertility rate is the mean number of live births a woman would have in her reproductive lifetime if she survived to age 50 and was subjected to age-specific fertility rates observed in a given year. This was expressed as the number of children per woman. The annual time series of total fertility rate from 2024 to 2063 was estimated using a Bayesian hierarchical model built on the theoretical model used by the United Nations to model fertility change (Alkema et al., 2011; Raftery, Alkema, et al., 2014; United Nations, 2024).

Figure 1. 1 Total fertility rate for Uganda: 1950-2024 estimates and 2025-2063 projections

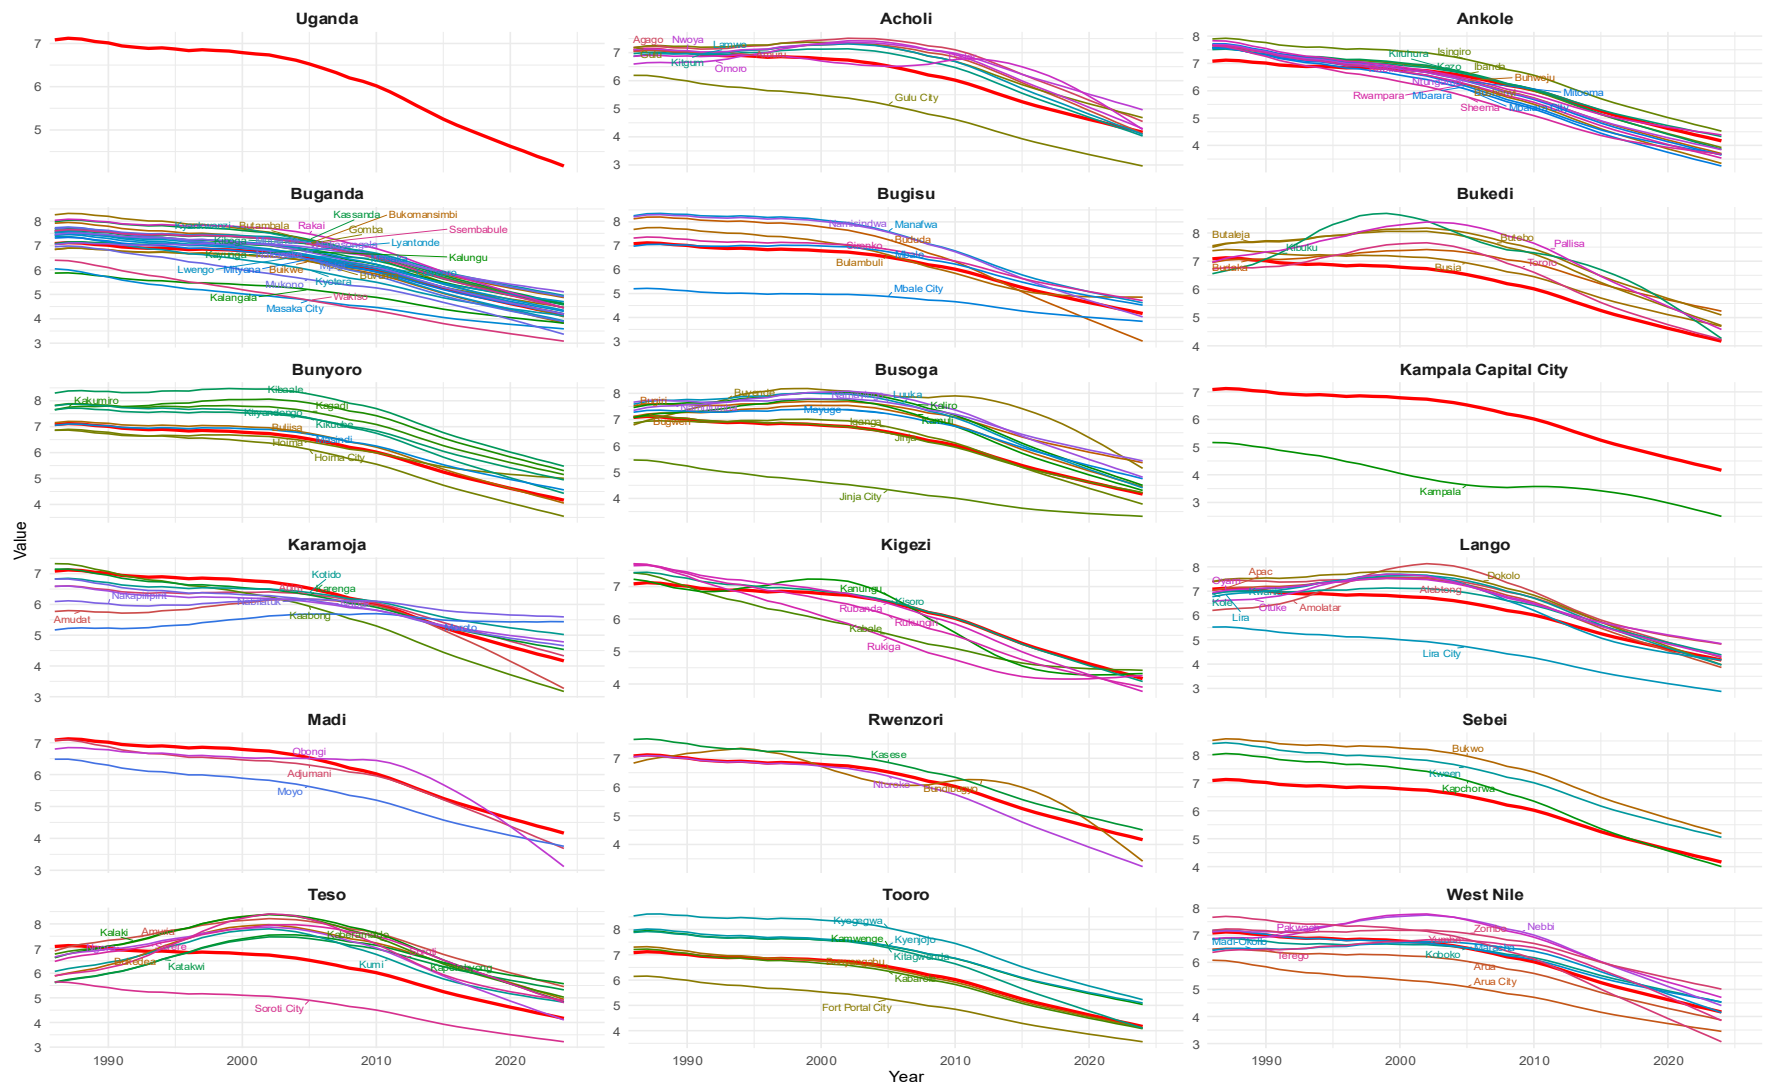

This model considers at the country level the biases and uncertainties associated with empirical estimates from different types of data sources, direct and indirect estimation methods, and other factors that contribute to systematic biases and non-sampling errors, and models future expected changes accounting for country-specific historical trends and the experiences of other countries with similar fertility levels in the past. Estimates were computed using an updated version of the Bayes TFR (Liu et al., 2023; Ševčíková, Alkema, et al., 2024; Ševčíková et al., 2011).

The median estimate of the total fertility rate was based on a sample of 1,000 trajectories of the model fitted to the observed data after considering various types of biases, and the 80% prediction intervals (PI) provided the upper and lower bounds. The results of the total fertility rate estimation and projections are shown in figure 1.1.

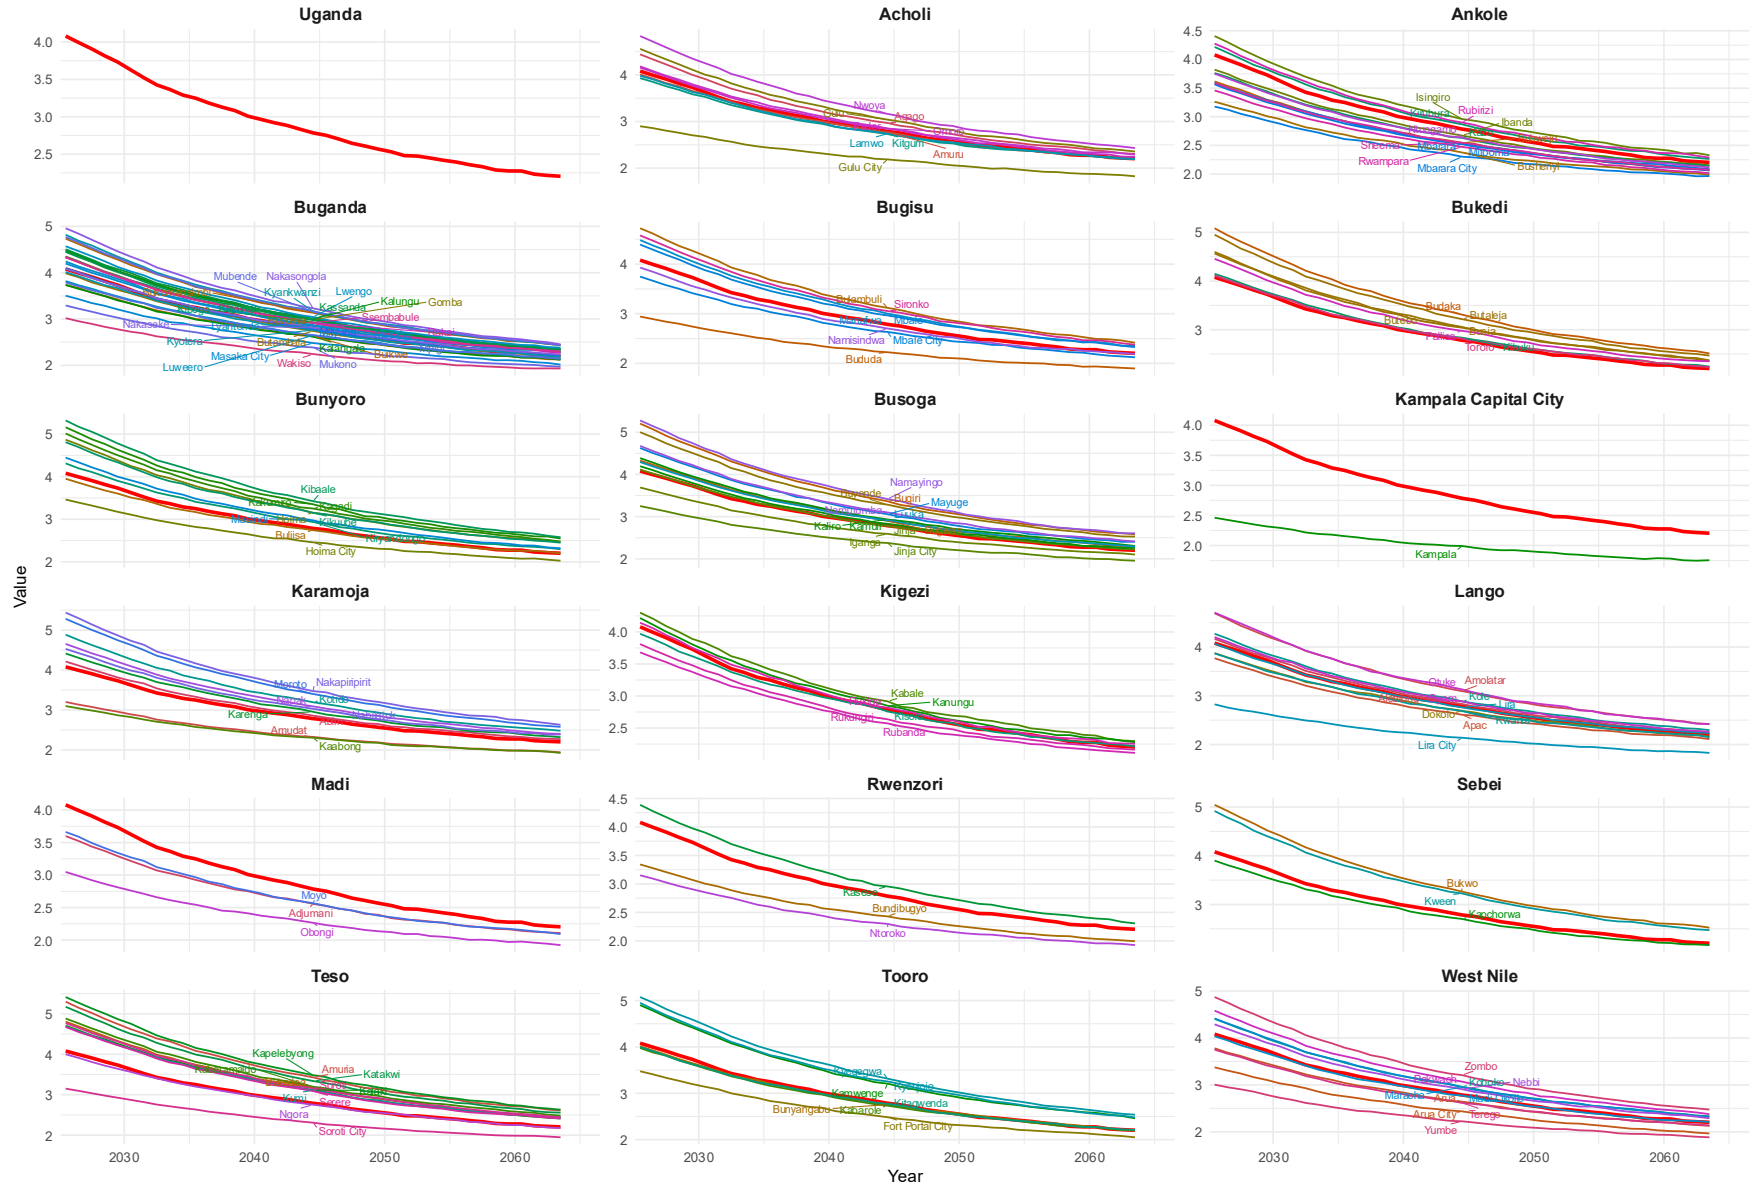

Estimates of total fertility rates at the district level were estimated for the 1986-2024 period (Figure 1.2, with the national average highlighted in bold red lines) using data from the 1991, 2002, 2014, and 2024 censuses, which provided information on births that occurred in the previous year before each census by age of the mother, as well as indirect estimates obtained using the reverse survival method (i.e., reconstructing past births and total fertility rate using the census age distribution of young children and accounting for their survival for the previous 15 years), and backdated estimates based on cohort-completed fertility derived from the mean number of children ever born for women aged 40 years and over and assumptions on their mean age of childbearing as implemented in the fertestr R package (Lima & Monteiro da Silva, 2021), and following standard demographic methods (Feeney, 1995; Moultrie et al., 2013; Ryder, 1983).

Figure 1. 2 Total fertility rate for Uganda: 1986-2024 estimates by sub-regions and districts

Projections of sub-national total fertility rates used the national-level projection results as a baseline reference and took into account the relationship between the fertility level in each district and the national average over time. The subnational annual time series of total fertility rates was calculated using bayesTFR with the Scale-AR(1) method (Ševčíková et al., 2018) by applying a district-specific, slowly changing scaling factor (i.e., ratio between district and country) to national fertility rate forecasts, allowing for a realistic degree of variation and convergence among districts within Uganda. For each district, an initial scaling factor was determined from the last observed TFR, relative to the national TFR. This region-specific scaling factor was then projected forward in time using a first-order autoregressive (AR (1)) process. Finally, these projected district scaling factors were applied to each of the 1,000 national TFR trajectories to generate 1,000 district TFR trajectories, allowing for realistic fluctuations and occasional crossovers between regions, while largely following the national trend. The results for the median projections are presented in Figure 1.3, with the national average highlighted by a bold red line.

Figure 1. 3 Total fertility rate for Uganda: 2025-2063 median projections by sub-regions and districts

Age-specific fertility rates at the national and district levels were estimated based on the 2024 census results by 5-year age groups for the initial reference period and graduated into single ages using calibrated splines (Schmertmann, 2014). Projections of future age-specific fertility rates used the UN probabilistic implementation from bayesPop (Ševčíková et al., 2016; Ševčíková, Raftery, & Buettner, 2024) by first computing the proportionate age-specific fertility rate (PASFR) pattern, and projecting these patterns in combination with each of the 1,000 trajectories of total fertility rates using a "convergence method" that blends two trends: one where the country's age pattern of fertility gradually moves towards a "global model pattern" (an average derived from low-fertility countries with later childbearing), and another where the country's recent observed national trend continues. The timing and speed of this convergence are linked to when a country is projected to complete its overall fertility transition and reach a stable low-fertility phase.

Finally, these projected proportionate age patterns (PASFRs) were applied directly to their respective TFR trajectories, ensuring that the distribution of births across a woman's reproductive age was consistent with the overall forecasted fertility level for each of the 1,000 projections, providing a detailed and realistic outlook on future childbearing. The same approach was applied at the sub-national level for each district.

The sex ratio at birth (SRB) is the ratio of male to female live births and typically remains stable across most populations, generally ranging between 1.03 and 1.07, with minor variations. Projections of the SRB from 2024 to 2063 were generated using a Bayesian hierarchical time-series mixture model, which accounts for both stochastic variations in observed SRB trends and the uncertainty inherent in SRB estimates (Chao et al., 2019, 2021) and takes into account at the country level the empirical information from birth histories of the various Uganda demographic surveys and recent births from censuses, and at the district level of sex ratios at birth from 1991, 2002, 2014, and 2024 censuses. Projections of the sex ratio at birth at the district level follow a similar approach as for the total fertility rate by modelling the relationship over time between each district and the national average.

2.3.2 Estimating mortality rates and life tables

Mortality assumptions required estimates and projections of the overall level of mortality summarized through life expectancy at birth by sex and some assumptions about the age patterns of mortality at both the national and subnational levels.

Life expectancy at birth is a summary of health and mortality. This tells us that the average number of years a newborn baby could expect to live if they experience the same death rates at each age as people did during a specific time period.

For Uganda, data on deaths reported by households 12 months before each census (1991, 2002, 2014, and 2024) were used to estimate mortality trends. These data were adjusted to better reflect deaths among infants and young children using indirect estimation methods, and estimates for adults were drawn from siblings and parental survival from Uganda Demographic and Health Survey.

At the district level, life expectancy estimates for 1991 to 2024 were computed using a special model life table system (Houle et al., 2022), taking into account adult HIV prevalence and ART coverage and indirect estimates of under-five mortality derived from children ever born and children surviving by age of mother and adult mortality between ages 15 and 60 based on household deaths, and indirect estimates based on maternal and paternal orphanhood.

Figure 2. 2 Male life expectancy at birth for Uganda: 1986-2024 estimates by sub-regions and districts

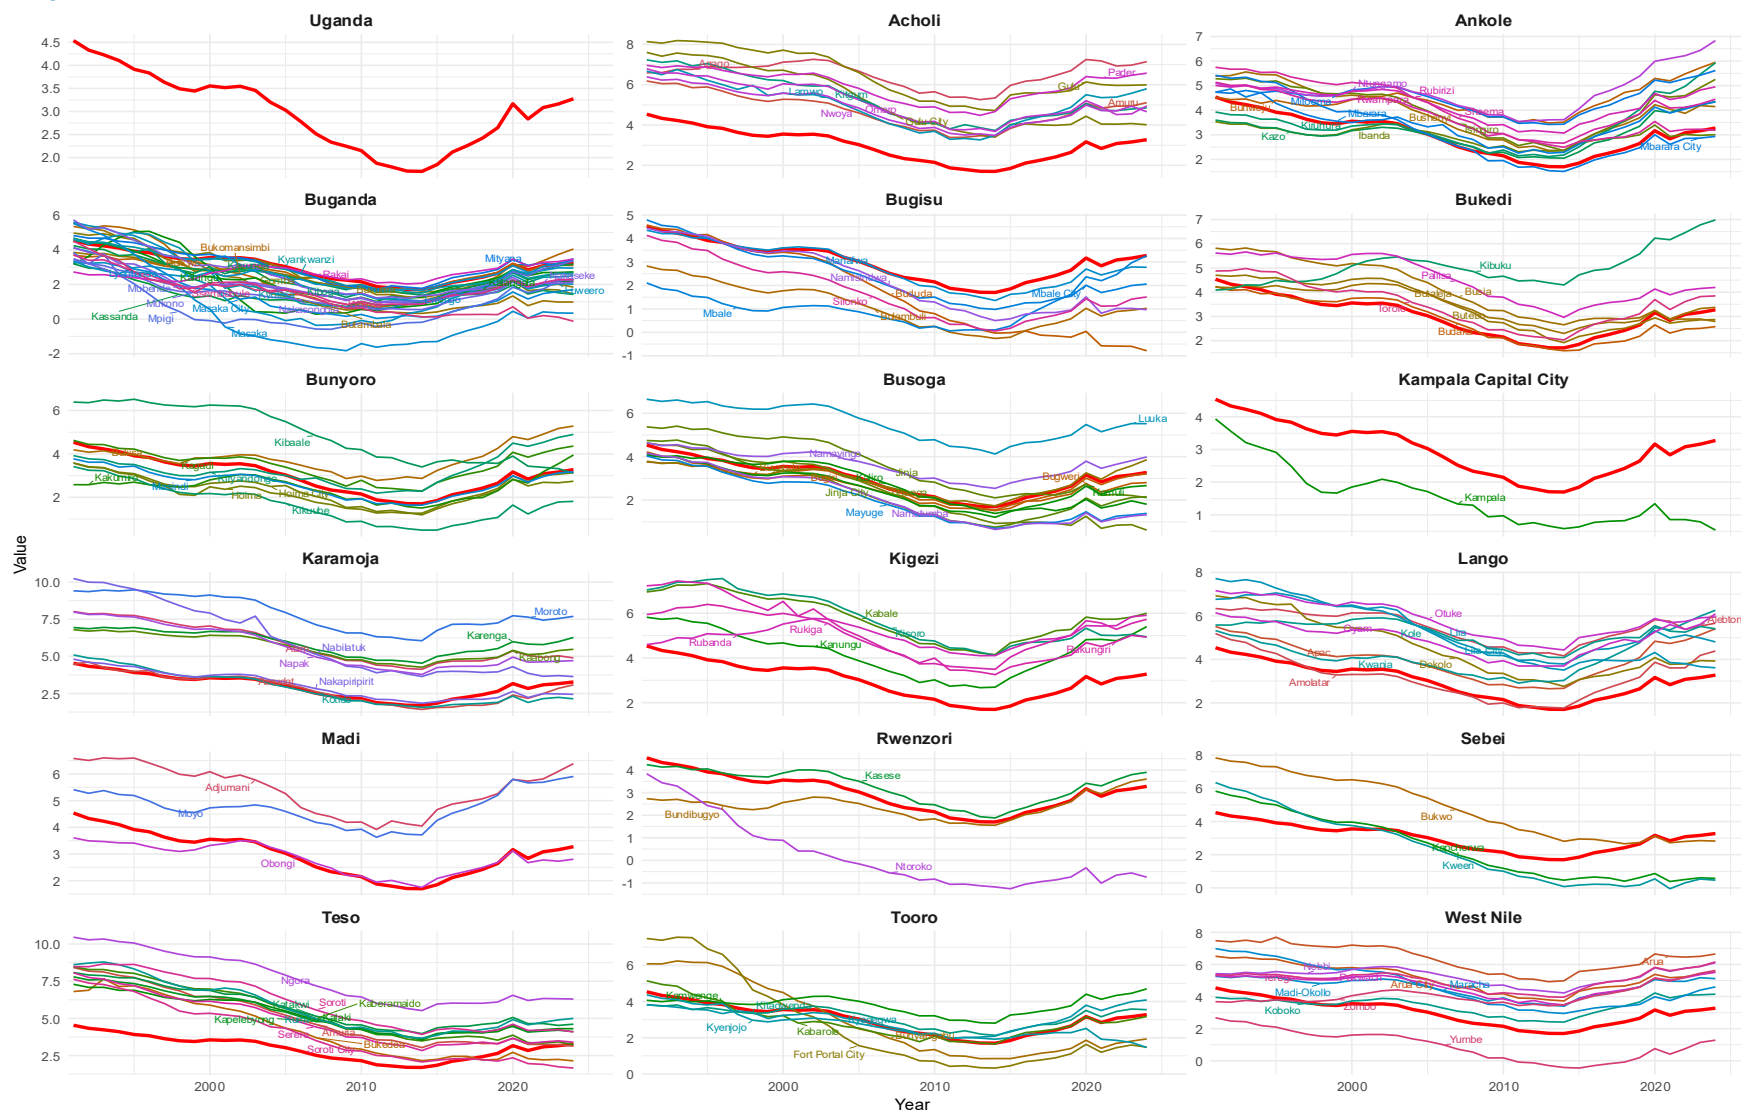

Figure 2. 3 Gap between female and male life expectancies at birth for Uganda: 1986-2024 estimates by sub-regions and districts (in years)

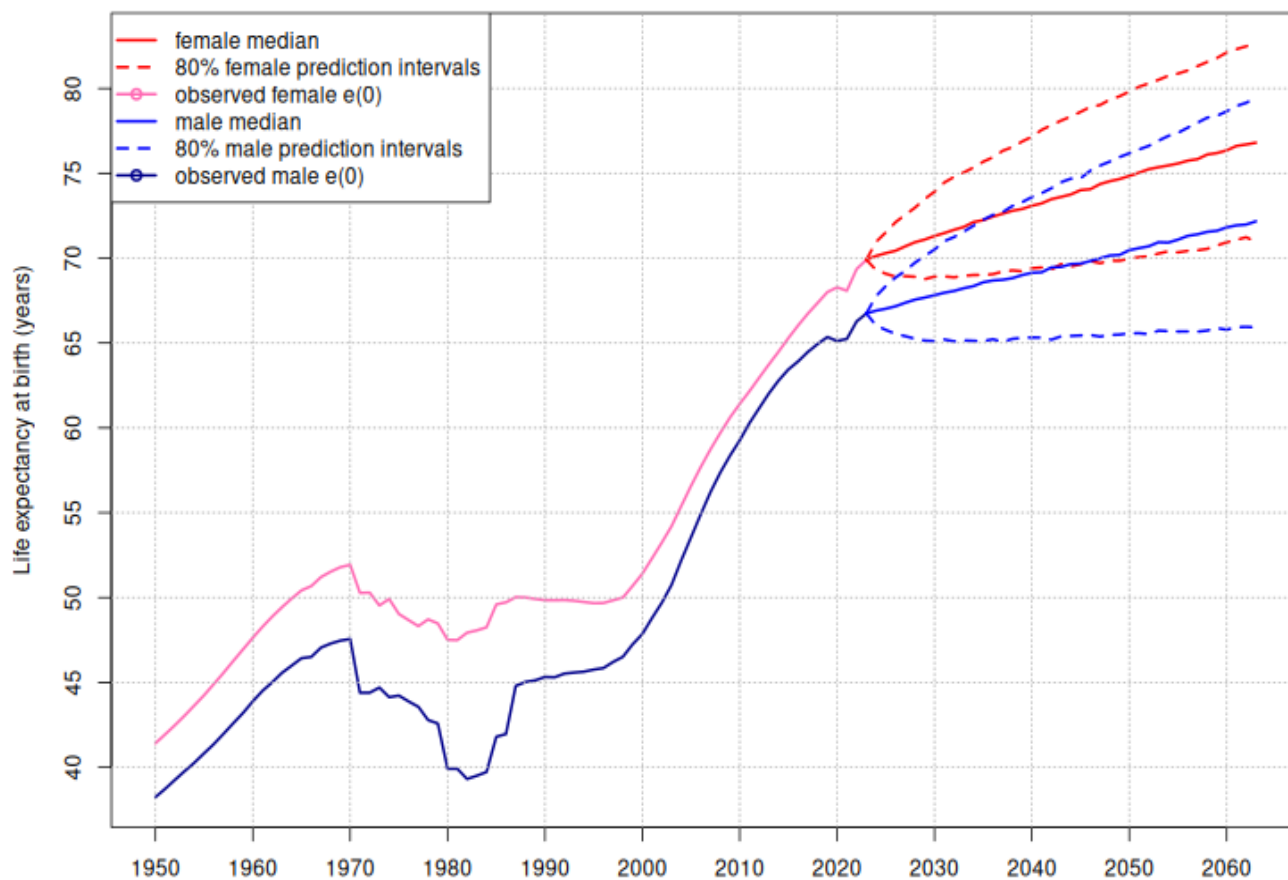

Life expectancy at birth was projected in two stages: (1) at the national level using the UN Bayesian probabilistic methods, first for females accounting for factors such as the HIV/AIDS pandemic and expanded coverage and access to ART, and then for males using the bayesLifeHIV package; and (2) at the district level using the results of the country projections for further guidance about expected levels and trends by sex for the national average.

For countries affected by HIV, such as Uganda, projecting life expectancy at birth involves a specialized, two-step probabilistic approach (United Nations, 2024). First, female life expectancy is projected using a statistical model that accounts for historical trends in life expectancy (Raftery et al., 2013), as well as the impact of HIV prevalence and coverage of antiretroviral therapy (Godwin & Raftery, 2017).

This model, implemented with the `bayes Life HIV` R package (Ševčíková, Godwin, et al., 2024), recognizes that while HIV initially reduces life expectancy, high ART coverage enables rapid recovery to pre-epidemic levels, followed by a steady increase, and generates 1,000 possible future paths to capture uncertainty. Second, to project male life expectancy, the method forecasts the "gap" between female and male life expectancy, which is the difference between their projected lifespans.

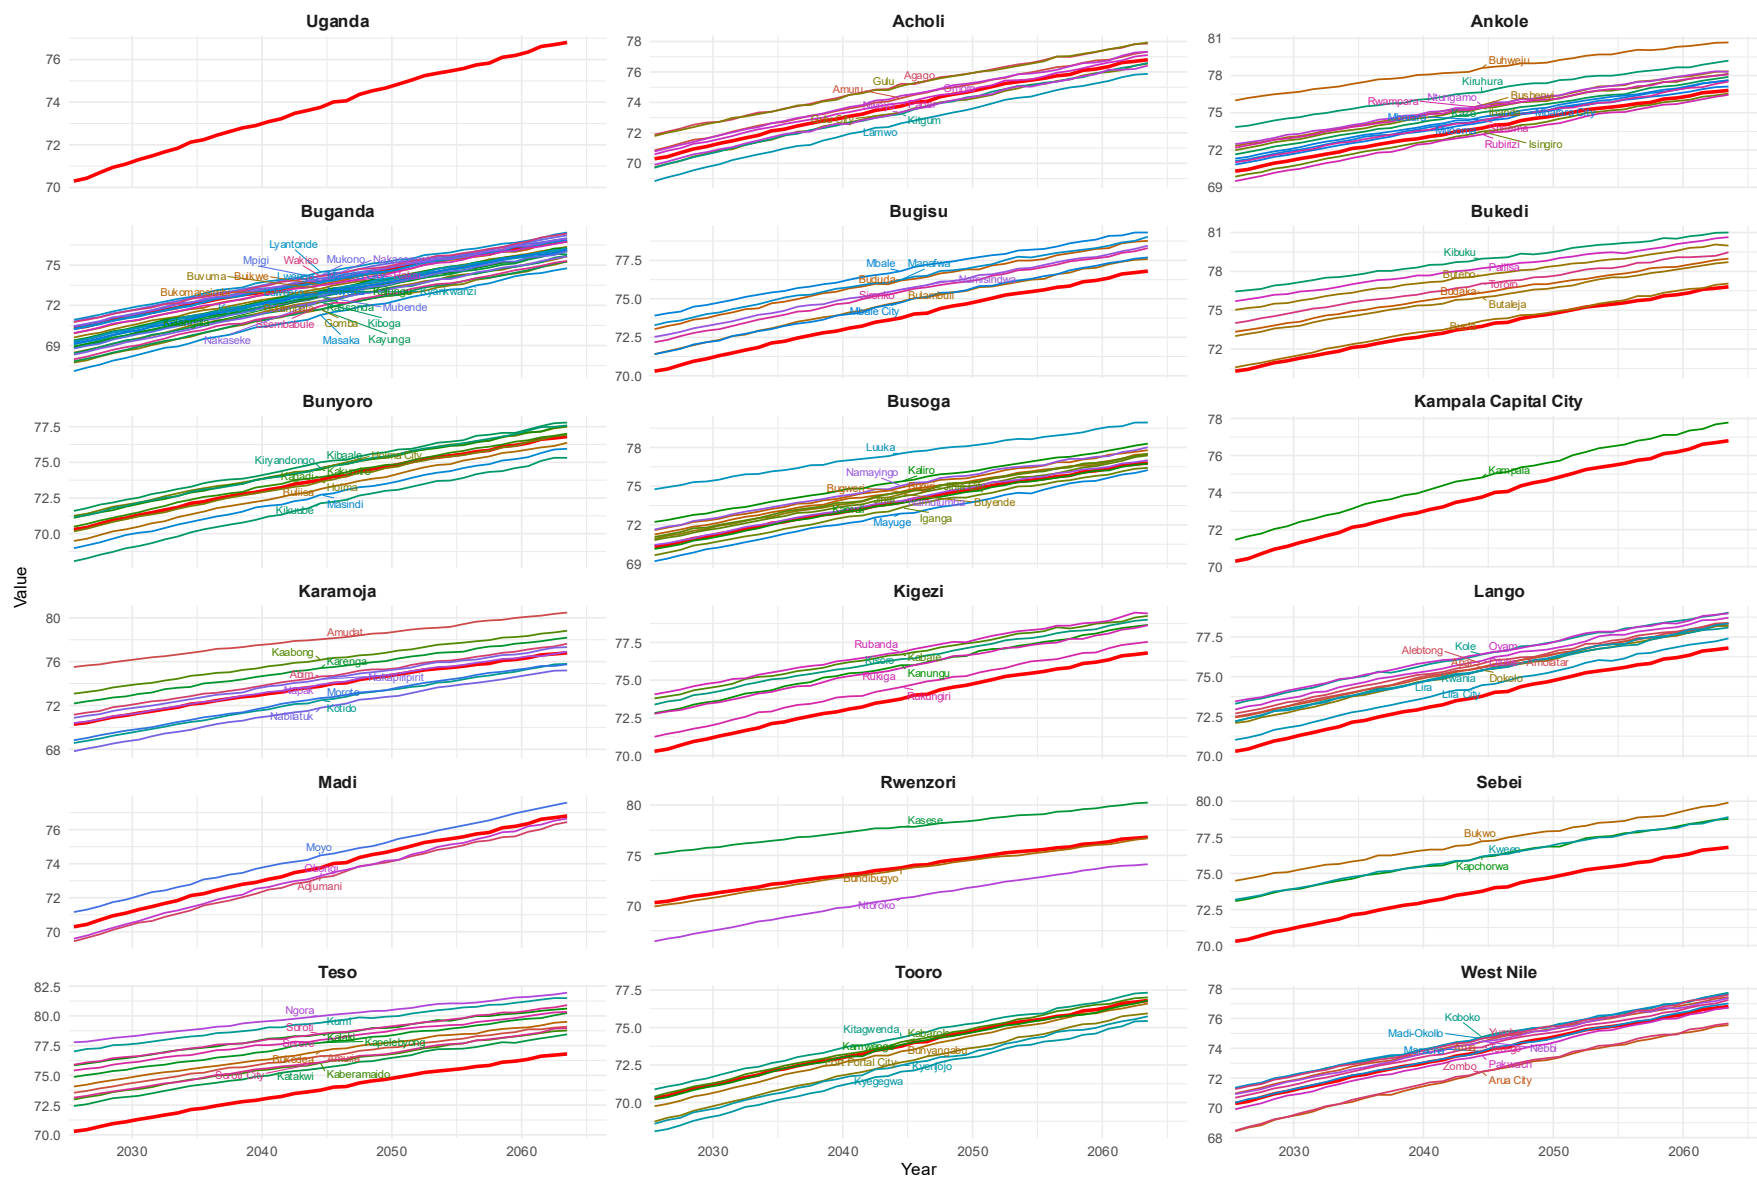

This gap is modeled based on the current female life expectancy and the gap in the previous period, as it has been observed to widen when life expectancy is low but then narrow once female life expectancy reaches approximately 75 years (Raftery, Lalic, et al., 2014). By combining these projected gaps with the female life expectancy trajectories, realistic and coherent projections for male life expectancy are derived, ensuring that the trends for both sexes remain plausible and consistent over time, often using the `bayesLife` R package (Ševčíková, Raftery, & Chunn, 2024).

Figure 2. 4 Life expectancy at birth for Uganda: 1950-2024 estimates and 2025-2063 projections

To project the life expectancy for each district within Uganda, a first-order autoregressive (AR(1)) statistical model uses 1,000 probabilistic forecasts for the entire country's life expectancy. For each of these national forecasts, the method then determined how a specific district's life expectancy will likely differ from that national average by projecting a district-specific difference or "gap." This difference is not fixed; instead, it changes over time through a statistical process (a first-order autoregressive, or AR(1), process), which means that the current district gap is influenced by its past value but also includes some random fluctuations that allow districts to realistically overtake or fall behind each other (crossovers). A key aspect of this method is that the size of these random fluctuations tends to decrease as the country's overall life expectancy increases, eventually leveling off. This aligns with the observed historical trends, where district disparities often narrow with increasing life expectancy. By applying these unique and dynamically projected district differences to each national life expectancy forecast, the method generates 1,000 possible future life expectancy paths for every district, providing a comprehensive and uncertain outlook.

Figure 2. 5 Female life expectancy at birth: 2025-2063 median projections by sub-regions and districts

For each of the 1,000 different future paths (trajectories) for life expectancy at birth, population projections begin by translating these life expectancy figures into detailed age-specific death rates for each age group. For countries where detailed mortality data are sparse like Uganda, the Pattern of Mortality Decline (PMD) method is used at the national level to project how the most recent death rates change across different ages. This method relies on a statistical model that captures typical age-specific patterns of mortality improvement and draws lessons from countries with high-quality historical data. It starts by fitting to a country's recent mortality patterns (from years not affected by crises like the COVID pandemic) and then gradually blends these patterns towards a general "model life table", in this case the Coale-Demeny North family, which represents a smooth, expected distribution of deaths across ages as overall life expectancy increases. This ensures that the projections remain realistic in the long term. At the district level, the Coale-Demeny North family model was used as the default pattern.

Once these age-specific death rates ($mx(t)$) are determined for a given trajectory and year, they are converted into probabilities of death (nx). These probabilities are crucial for the construction of a life table. This life table, for that specific trajectory and year, provides the survival ratios (Sx) needed to "survive" the population. The cohort-component method then uses these survival ratios to calculate how many people from each age and sex group survive until the next year, thus determining the projected population at the end of the calendar year. This entire detailed process was repeated for each of the 1,000 unique life expectancy trajectories to capture the range of possible future population outcomes.

2.3.3 Estimating net migration

Country estimates were based on the annual number of international immigrants and emigrants obtained from the 2024 census for the previous 5-years, complemented by annual estimates of refugees from UNHCR, where the net number of migrants is obtained as immigrants minus emigrants. District estimates relied on these estimates of international migration combined with the annual number of domestic migrants who moved in or out of each district (based on place of previous residence in the previous 5-years) where the number of net migrants is obtained as (international and domestic immigrants) minus (international and domestic) emigrants.

Projections are based on past estimates of crude net migration rates computed using the number of net migrants and total population. After reviewing the estimated recent net migration rates from the 2024 census for all districts, it was found that the figures for some of the newer districts, those recently created by splitting from larger ones were less reliable. In these cases, it was considered more accurate to use the migration estimates from the original, larger "parent" districts.

Figure 2. 7 Crude net migration rate: 1991-2024 estimates by sub-regions and districts (per 1,000 person)

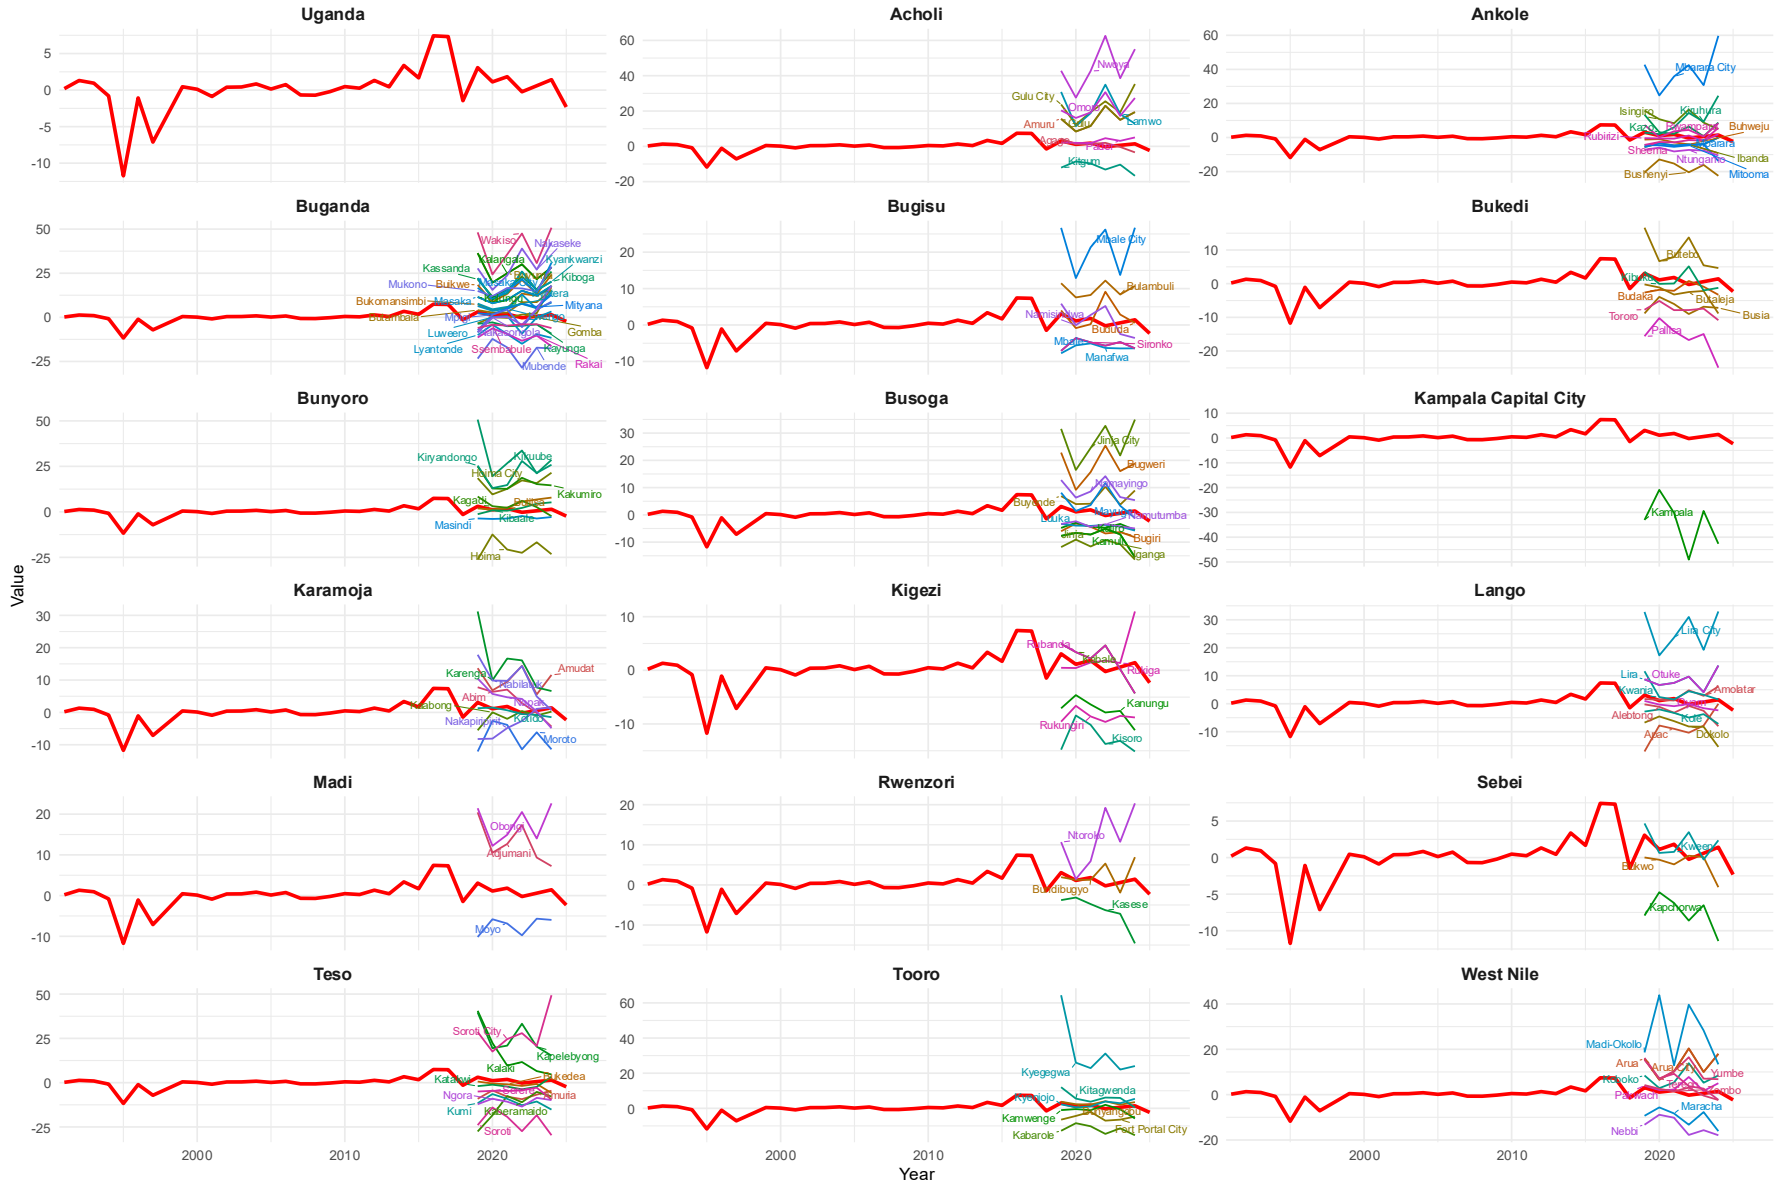

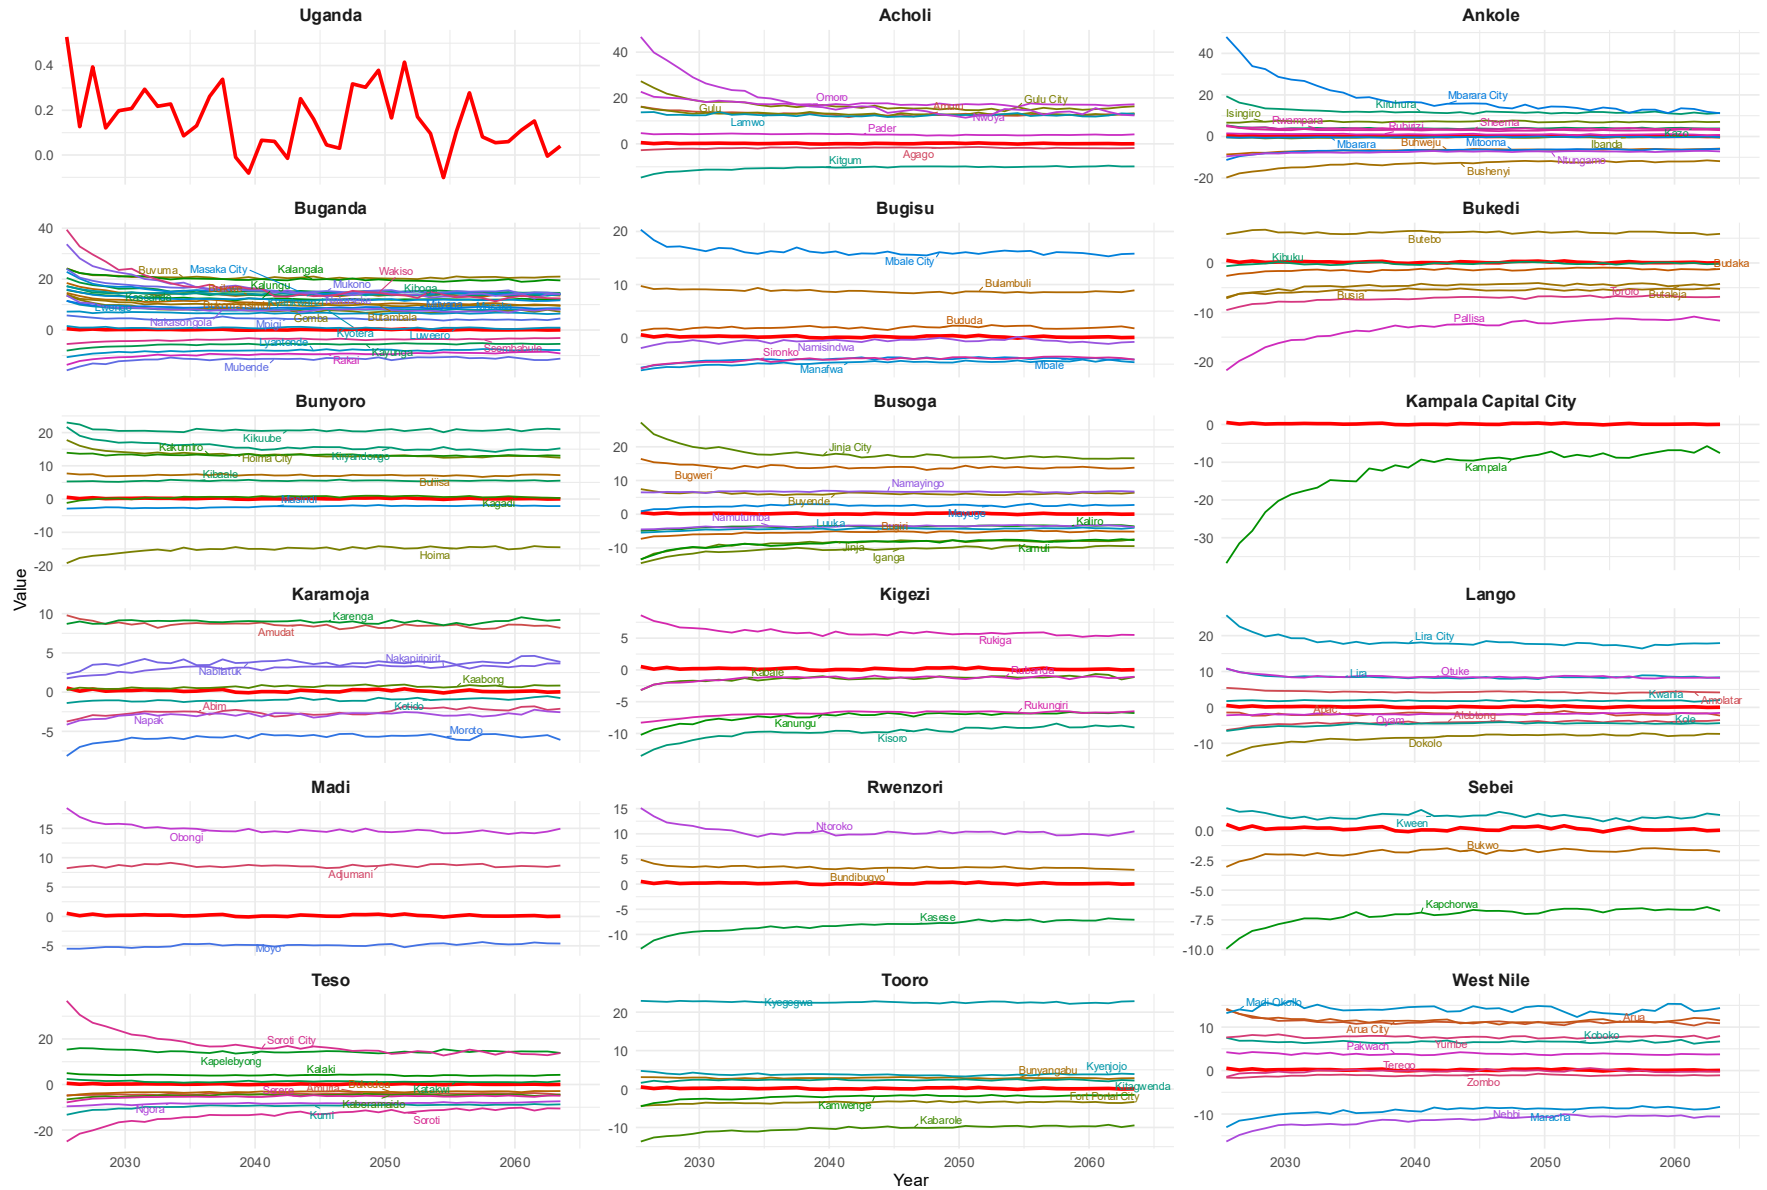

Figure 2. 8 Crude net migration rate for Uganda: 1991-2024 estimates and 2025-2063 projections

Figure 2. 9 Crude net migration rate: 2025-2063 median projections by sub-regions and districts (per 1,000 person)

For a country like Uganda, projecting future net migration—the difference between people moving in and out—is particularly complex because migration data are often incomplete, and trends can shift rapidly due to various factors such as economic changes, conflicts, or refugee movements. To address this challenge in national population projections, the United Nations uses a probabilistic approach involving an autoregressive model (AR(1)). This model analyzes a country's past crude net migration rates (for Uganda, using data from 1950-2025) to forecast future trends, essentially predicting the next year's migration based on the previous years, while also considering long-term averages and random fluctuations. Projections at the district level use the annual changes in crude net migration rates obtained from the 2024 census for the previous 5-years. All computations were performed using the BayesMig R package (Azose et al., 2024), and 1,000 projections of the crude net migration rates were generated for the country and each district.

For projection purposes, the projected annual number of net migrants was distributed by age and sex, assuming that the underlying patterns by age and sex follow a simplified model age schedule, such as the Rogers-Castro model, which captures the typical age profile of migrants (concentration in young adult ages) as used by the United Nations (Riffe et al., 2022; United Nations, 2024), and implemented in bayesPop (Ševčíková, Raftery, & Buettner, 2024).

2.3.4 Probabilistic population projections and future vital counts

For a country such as Uganda, predicting future population changes involves a sophisticated approach called probabilistic projections, where instead of just one prediction, 1,000 different possible future paths are generated for key demographic factors such as births, deaths, and migration, as explained in the previous sections. All 1,000 projected pathways for fertility, mortality, and migration are then fed into a demographic accounting framework through the cohort-component method to project the population year by year, by age, and sex, for each of the 1,000 possibilities. The same approach was used for each of the 146 districts. All probabilistic population projections were computed using the `bayesPop` R package (Ševčíková & Raftery, 2016; Ševčíková, Raftery, & Buettner, 2024), specifically designed to perform these computations and allow users to analyze and visualize the resulting probabilistic distributions.

For population projections, median and prediction intervals (PIs) are crucial tools for summarizing a wide range of possible future outcomes and quantifying the inherent uncertainty in demographic trends. Instead of producing a single "best guess" for the future population, probabilistic projections generate a large number of distinct future paths, known as trajectories, for key demographic components such as fertility rates, mortality rates (life expectancy at birth), and net migration rates.

The following statistical measures were computed for this report:

- The Median represents the central or most typical trajectory among all generated future paths for a given demographic indicator or population quantity (e.g., total population, population by age, and sex). For example, if 1,000 trajectories are generated, the median trajectory is one where half (1,000) of the projected paths are above it and half are below it.
- Prediction Intervals (PIs) provide a range within which a specified percentage of the projected trajectories are expected to fall, thus directly quantifying the uncertainty. To compute an 80% prediction interval for any given year, the individual values from all 1,000 trajectories were ranked from lowest to highest. The lower bound of the 80% PI was then identified as the value below which 10% of the trajectories fell (i.e., the 10th percentile), and the upper bound was the value above which 10% of the trajectories fell (i.e., the 90th percentile). This means that 80% of all the projected outcomes lie within this range.

As the projection horizon increases, meaning that projections extend further into the future (e.g., from 2025 to 2063), the prediction intervals naturally widen. This widening trend directly reflects the increasing uncertainty associated with long-term demographic forecasting. The further out in time one projects, the more opportunities for small, random fluctuations in fertility, mortality, and migration rates to accumulate, leading to a broader range of possible future population sizes and structures. By presenting both the median and 80% prediction intervals, probabilistic projections offer a more comprehensive and realistic understanding of future demographic trends than single-value deterministic projections do.

2.3.5 A Coherent System of Subnational Projections

A robust system of subnational projections must be more than a collection of independent district forecasts. The projections must be consistent with each other and sum up to the national totals. This is achieved through a hierarchical approach, where national projections serve as the control totals for the sum of the subnational parts.

1. **Hierarchical Approach:** The projection process was conducted in a top-down manner. First, national-level probabilistic projections for the population and its components are generated. Subsequently, district-level projections for fertility, mortality, and migration were produced based on their modeled relationship with national trends. These district-level components were then used in separate cohort component models for each of the 146 districts. For each of these sets of projections, the initial median and 80% prediction intervals were computed.
2. **Constraining to National Totals:** Due to the stochastic nature of the models, the initial sum

of the 146 district projections for any given age-sex group will not perfectly match the independently projected national total for that same group. To ensure consistency, a final adjustment step is required.

- For the Median Projection: A standard demographic technique known as Iterative Proportional Fitting (IPF), implemented in R using the mipfp package, was used. IPF, also known as raking or the RAS algorithm, is a mathematical procedure that adjusts the cells of a multidimensional table (in this case, a 146 districts × 101 ages × 2 sexes matrix) to match a set of known marginal totals (the national population by age and sex), while preserving the internal association structure of the table as much as possible. This means that the relative population differences between districts for any given age-sex group are maintained, ensuring that the adjustment does not distort the underlying demographic patterns at the subnational level. This is a standard method used to ensure internal consistency.
- For the Prediction Intervals: For upper and lower bounds of the 80% prediction intervals, the subnational results by age and sex were rescaled proportionately by a common factor equal to the national-to-aggregate ratio used to adjust the median to preserve the relative dispersion.

This two-pronged approach ensures that the entire projection system, from the median to the uncertainty bounds, is fully coherent from the district level to the national level.

2.3.6 Projection Assumptions and Scenarios

Population projections are based on assumptions related to the future behavior of fertility, mortality, and migration rates. Because no one can accurately predict the future, multiple scenarios (low, medium, and high) are typically produced to reflect varying assumptions. The medium scenario is generally considered the most probable course of future population growth and structure and is often recommended for use by planners. Other scenarios usually represent the maximum or minimum plausible outcomes.

This new set of projections for Uganda uses the UN's probabilistic methods, which show not just one possible future, but a range of outcomes to reflect uncertainty. Instead of giving a single number, the projections include an 80% prediction interval, meaning that in eight out of ten possible futures, the population falls within this range. There is still a 1 in 10 chance that it could be higher than the upper limit or lower than the lower limit. The medium scenario represents the most likely outcome, the middle value (i.e., median) from 1,000 different simulations of future trends.

Table 1: Summary of population projections Assumptions

	Total Fertility Rate	Life Expectancy at birth (Males)	Life Expectancy at birth (Females)	Life Expectancy at birth (Total)
2025	4.1	67.0	70.3	68.7
2026	4.0	67.2	70.4	68.9
2027	3.9	67.4	70.7	69.1
2028	3.8	67.6	70.9	69.3
2029	3.7	67.7	71.1	69.5
2030	3.6	67.8	71.3	69.6
2031	3.5	68.0	71.5	69.8
2032	3.4	68.1	71.7	69.9
2033	3.4	68.2	71.8	70.1
2034	3.3	68.4	72.1	70.3
2035	3.2	68.6	72.2	70.5
2036	3.2	68.7	72.4	70.6
2037	3.1	68.7	72.6	70.7
